

Gene Flow Modelling by Correlated Random Walk

E. L. Foster*, D. M. Chan[†] and R. J. Dyer[‡]

September 8, 2013

Abstract

The understanding of gene movement in plant species is critical to the management of both plant and animal species reliant on that plant. Pollen is the mechanism by which plants pass their genetic material from one generation to the next. Pollen dispersal studies have focused primarily on purely random diffusion processes, while this may be a good assumption for species pollinated mainly by abiotic means, such as wind, it is most likely an over simplification for species that are pollinated by biotic means, such as insects [3].

Correlated random walk (CRW) models are a model of animal movement [9] and have been successfully used to explore the movement of animals in varying ecological contexts [1]. An agent-based model (ABM) is developed to describe pollen movement via insects as a correlated random walk (CRW). This model is used to explore how insect path lengths and pollen distribution are affected by the varying turning angle and plant density.

1 Introduction

Pollination is one of the most critical and complicated biological processes on the planet. It is an important part of every ecosystem, and is essential to creating diversity and reproduction within plant species. There are numerous different mechanisms by which pollination occurs. Some of which are abiotic through movement of fluids such as the wind or water, while others are biotic using animals, often insects, to move pollen from one plant to another. Studying this process directly is generally impossible if not impractical. There are indirect methods developed to infer how pollination diffuses genes among plants, see .

In this study a model is created to simulate the dispersion of pollen between plants where calculations are done to measure the differences between movement

assumptions as well as changes in plant density. The model mimics both abiotic and biotic movement in order to compare the two types of diffusion. There are numerous factors which make this critical process complex to understand as well as to study.

Understanding the pollination process may allow for optimization of the number of pollinators used for crop pollination, thereby reducing cost to farmers. Additionally, a better understanding of the pollination process can lead to the prevention of cross pollination of genetically modified plant species and non-genetically modified plant species.

Pollen dispersal studies, for both abiotic and biotic pollen dispersal, have focused primarily on purely random diffusion processes, while this may be a good assumption for species pollinated by wind, it is most likely an over simplification for species that are pollinated by animals [3]. A purely random diffusion process in two dimensions accurately predicts pollen dispersal at a particular time, but only for a purely random walk [2].

Pollen movement via biotic means may not be a purely random process and therefore would not diffuse in a purely random fashion. In fact, there are several examples of pollinating animals that exhibit *trap line* behavior [3]. That is, they follow a particular route as they collect pollen. Thus the movement of animals as they carry pollen may follow more direct paths and therefore would not result in a purely random diffusion process [5]. Such behaviors result in dispersal that does not mimic a purely random walk. The movement of animals can be described as a correlated random walk (CRW), where the correlation is based on the distribution and magnitude of random turning angles. In this way the previous direction of travel influences the direction of travel for the next step.

A purely random walk can be used to model a purely random diffusion process such as Brownian motion [4]. While a CRW can be used as a general model of animal movement [9] and have been successfully used to explore the movement of animals in varying ecological contexts [1]. CRW models have been used to model the dispersal of bark beetles, Coleoptera: Scolytidae [2], deterministic diffusion [10], and fractional Brownian motion [6].

An agent-based model (ABM) describing pollen movement via animals as a correlated random walk (CRW) is introduced. ABMs consist of agents that interact with each other and their environment. ABMs allow for simulations that consist of a large number of interacting parts that would not be easily constructed otherwise [7]. Agents can represent things such as people, animals, organizations, etc. that interact with each other and their environment. The environment in an ABM can represent things such as a spatial domain, or a network in which the agents are connected to each other [8]. ABMs have been used in modeling racial segregation, supply chain dynamics, and neural networks [8].

Consequences of the CRW and the interaction of animals with plants is examined using computer simulations. Two animal statistics (*average path distance* and *average maximum distance*) and three plant statistics (*average pollination distance*, *average maximum pollination distance*, and *average weighted diversity*

of fathers) are presented. Turning angle and plant density are varied and their effects on animals paths and pollen distribution are examined.

It is shown that bias can be introduced by describing animal movement as a purely random walk. That is, there is a significant difference between the model outcomes for a purely random walk as compared to a CRW. Thus, modeling animal mediated pollen dispersal by way of a purely random diffusion process is likely to result in errors in the approximation of the extent of pollen dispersal.

2 Methods

In this study an agent-based model simulates the pollination of trees in a forest. The model assumes continuous space and consists of two interacting agents; *animals* and *plants*. We consider different plant densities to determine what effect density has on the distribution of pollen. The plants have a limited supply of pollen that can be gathered by animals. Animals transport the pollen across the environment using particular movement rules to deliver the pollen to other plants. The animals movement is determined by a correlated random walk. At each step of their movement they search the local neighborhood for plants where they will collect additional pollen and deposit pollen.

2.1 Movement

Movement in the model is centered on the animals, since plants do not move. Pollen is carried by the animals from one plant to another. At each step the movement of an animals is conducted in two stages: *searching* and *movement*. First, the animal checks a neighborhood of radius r to see if there are any trees within the neighborhood. If there are one or more trees, the animal chooses the closest tree. If there are two or more trees equidistant from the animals current location then one of those trees are chosen randomly. The animal then moves to the location of the chosen tree.

If there are no trees within a distance r from the current location of the animal, the animal then moves according to a correlated random walk. For the correlated random walk the animal chooses a direction based on a probability distribution in which the higher probabilities are centered about the animal's current direction, see Subsection 2.1. The animal then takes a step of length between 0 and 1 distributed uniformly in the new chosen direction. This length is denoted by $s_j^{(i)}$, which is the j^{th} -step taken by the i^{th} animal.

Figure 1: Turning Angle for (a) uniform distribution and (b) depiction of what a path may look like.

Alternatively, if the animal is already at a plant, the animal picks a random direction uniformly and takes a step of size $r + 1.0$. This will ensure that the animal will not immediately return to the same plant on the very next step.

2.2 Pollination

When an animal is on a plant, it collects pollen, distributes pollen, and consumes food. Each plant contains a number of flowers, ϕ , from which an animal may obtain pollen. When an animal visits a plant it picks up pollen from one or more flowers. The number of flowers from which an animal can obtain pollen is determined by the total number of flowers on a plant, the fraction of flowers in bloom at any one time (a), the number of times (j) the plant has previously been visited by an animal, and the maximum fraction of flowers available for pollination (η). The formula for the number of total flowers available for visitation during a k^{th} visit to the j^{th} plant ($f_{j,k}$) is given by

$$f_{j,k} = \phi \cdot a \cdot \eta^k. \quad (1)$$

It is assumed that the amount of food eaten and the amount of pollen collected is proportional to the number of visited flowers. An animal collects pollen and eats from every flower that it visits, and so the amount of pollen collected and the amount of food eaten is proportional to the equation (1). Let $f_{j,k}^{(i)}$ be the number of flowers visited by the i^{th} animal during the k^{th} visit to the j^{th} plant then the amount of pollen/nectar in the i^{th} animal's stomach after m plant visits is given by

$$c_m^{(i)} = \sum_{j=0}^m \beta f_{j,k}^{(i)}, \quad (2)$$

where β is the proportionality constant for the amount of pollen collected at a plant. Each animal has a maximum amount of food they will ingest, c_{max} , at which time they will stop search for food and return to their lair. limited

The fraction, α , of all flowers are pollinated, and the associated probability that a flower is pollinated, ρ , are related by the equation,

$$\alpha = \rho \cdot \hat{f}_k. \quad (3)$$

Using equation (2) and (3) we can determine the probability that a flower is pollinated, ρ , by the formula

$$\rho = \frac{\alpha}{\phi} \cdot \frac{1 - \eta}{a \cdot \eta}.$$

When a flower is pollinated it must determined which previous plant donated the pollen. Each flower visited is recorded and is available to pollinate the current flower, except those flowers that are on the same plant. Self-pollination, is not considered, because the likelihood of self-pollination is low due to mechanisms that impedes self-pollination. Each flower considered has an equal likelihood of pollinating the current flower.

2.3 Time and Stopping Criteria

The velocity an animal travels (v) is assumed to be constant, as well as the time spent on a plant (t_{plant}). The travel time for an animal is then given by the formula

$$t^{(i)} = \frac{s^{(i)}}{v} + T^{(i)} \cdot t_{plant},$$

where $T^{(i)}$ is the number of plants visited by the i^{th} animal. If we let the maximum allowable travel time be t_{max} , then once $t^{(i)} \geq t_{max}$ or $c_m^{(i)} \geq c_{max}$ the animal is removed from the simulation. t_{max} is based on the optimal searching time during the day. When there are no animals left the simulation terminates.

2.4 Model Statistics

To best explore the inherent differences between biotic and abiotic pollination this study focuses on the effects of movement as well as the effects of plant density. In order to quantify these differences we measure statistics that are inherent of the animals: *Average Path Distance*, *Average Maximum Distance*, and those of the plant: *Average Pollination Distance*, *Average Maximum Pollination Distance*, *Average Weighted Diversity of Fathers*. The calculations of these statistics are given in the Table 1.

In these equations it is assumed that b is the total number of animals, n is the total number of plants, $(x_{1,0}^{(i)}, x_{2,0}^{(i)})$ is the starting location of the i^{th} animal, $(x_{1,j}^{(i)}, x_{2,j}^{(i)})$ is the location of the i^{th} animal after j steps, $\tau^{(i)}$ is the total number of seeds for the i^{th} plant, $\Delta\tau^{(i)}$ is the number of different fathers contributing pollen to the i^{th} plant, and $F_{j,i}$ is the number of times the j^{th} father contributed pollen to the i^{th} plant.

Measure	Equation
Average Path Distance	$\bar{s} = \frac{1}{b} \sum_{i=1}^b \sum_{j=1}^n s_j^{(i)}$
Average Maximum Distance	$\bar{M} = \frac{1}{b} \sum_{i=1}^b \max_j \sqrt{(x_{1,0}^{(i)} - x_{1,j}^{(i)})^2 + (x_{2,0}^{(i)} - x_{2,j}^{(i)})^2}$
Average Pollination Distance	$\bar{p} = \frac{1}{n} \sum_{i=1}^n \left(\frac{1}{\tau^{(i)}} \sum_{j=1}^{\tau^{(i)}} \sqrt{(x_1^{(i)} - x_1^{(j)})^2 + (x_2^{(i)} - x_2^{(j)})^2} \right)$
Average Maximum Pollination Distance	$\bar{P} = \frac{1}{n} \sum_{i=1}^n \max_j \sqrt{(x_1^{(i)} - x_1^{(j)})^2 + (x_2^{(i)} - x_2^{(j)})^2}$
Average Weighted Diversity of Fathers	$E = \frac{1}{n} \sum_{i=1}^n 1 / \frac{1}{(\tau^{(i)})^2} \sum_{j=1}^{\tau^{(i)}} F_{j,i}^2$

Table 1: Equations

Parameter Description	Symbol	Value	
Total number of animals	b	1,000	fixed
Maximum time	t_{max}	1,200 seconds	fixed
Fraction of blooms at one time	a	0.2	fixed
Maximum fraction of available flowers	η	0.75	fixed
Search radius	r	1.0	fixed
Number of flowers per plant	ϕ	100	fixed
Probability of pollination	ρ	0.4286	calculated
Number of plants	n	1000	fixed
Time spent at each plant	t_{plant}	100 seconds	fixed

Table 2: Parameter Values

3 Results

The following results are based on simulations of the model with parameter values given in Table 2. These parameters are based on field data estimates from the VCU Rice Center (unpublished). The grid size was 101 patches by 101 patches.

The standard error was calculated by dividing the sample standard deviation by the square root of the total number of samples. The standard errors were all less than 1% on average, so will not be shown due to the small size.

Determining the distance animals travel during a foraging trip is important factor for their survivability. In order for an animal to survive it must find enough food foraging without losing too much energy. In this study the density of plants is varied, which can directly affect the amount of foraging the animals will be able to achieve in a set amount of time. The higher the density the

Figure 2: Average Path Distance vs. Turning Angle for Various Plant Densities

greater the potential for the animal to forage. The maximum angle is also varied. The relationship of this angle with respect to foraging is a more complicated one. In terms of foraging, a very small maximum turning angle may not result in successful foraging due to the paths are too linear. On the other hand, a maximum turning angle which is too large can result in searching patterns that repetitively cover the same area over and over again.

In Figure 2 the average distance traveled for each animal decreases with increasing density due to higher foraging success. In this situation the animals will spend more time on plants since they can find plants more readily. The maximum turning angle does not have a large effect on on the distance. There is a modest effect of maximum turning angle on low plant density where the larger the angle increases the average distance due to less success of foraging.

The average maximum distance traveled by animals, see Figure 3, is affected by both the turning angle and plant density. As with the average path distance, the maximum distance decreases with higher density which decreases the overall travel time for the animals. Though in this case due to the movement patterns the angle has a large effect on maximum distance especially at lower densities. As the maximum angle decreases the animals are more likely to travel directly away from their starting points increasing the maximum distance traveled.

For a plant density of 0.01 and $AMT = 0^\circ$ the average maximum distance is quadruple of the average maximum distance for a plant density of 0.01 and $AMT = 180^\circ$. For a higher plant density of 0.15 the average maximum distance is 50% larger. Thus, a purely random diffusion process results in shorter average maximum distances as compared to smaller turning angles, and as was seen with the average pollination distance the effect of turning angle is more pronounced for smaller plant densities. Again, this is expected since for higher plant densities the animal direction is reset more often and therefore the animal path becomes more and more like a purely random walk.

The average pollination distance, see Figure 4, decreases with increasing density due to the greater likelihood of pollinating nearby trees. As with the

Figure 3: Average Maximum Distance vs. Turning Angle for Various Plant Densities

Figure 4: Average Pollination Distance vs. Turning Angle for Various Plant Densities

Figure 5: Average Maximum Pollination Distance vs. Turning Angle for Various Plant Densities

average maximum distance, as the maximum angle decreases the animal is likely to travel farther from its initial position which allows for longer pollination distances.

For a plant density of 0.01 and $AMT = 0^\circ$ the average maximum pollination distance is approximately triple of that for the same plant density and $AMT = 180^\circ$. Additionally, for plant density of 0.15 and $AMT = 0^\circ$ the average pollination distance is approximately double of the average pollination distance for the same density and $AMT = 180^\circ$. Clearly, the average pollination distance for wind dispersal is less than that of an average pollination distance for an animal that follows a straighter path for any of the simulated plant densities.

The average maximum pollination distance has a much more complicated relationship with density and maximum turning angle, see Figure 5. The average maximum pollination distance decreases as maximum turning angle increases from 0° to 180° across all densities. This is due to animals covering a shorter distance for higher turning angles, and therefore the plants that are visited will be closer together on average.

Additionally, we see that the resultant average maximum pollination distance for a purely random diffusion process is marketably lower than those for correlated random walks resulting in straighter animal paths. Thus, wind dispersal will result in an average maximum pollination distance that is less than the average maximum pollination distance for a correlated random walk. Thus, one might expect that wind dispersal of pollen results in a smaller areal extent of gene flow as compared to animal mediated gene flow.

The density affects the maximum pollination distance in a more complex fashion. The higher the density the more gradual the decrease is in the maximum pollination distance as the maximum turning angle increases. Whereas for lower densities this decrease is much larger. This is likely due to the fact that at lower densities pollination occurs less frequently with a larger variability of maximum pollination distances.

In general there is a small decrease in the average weighted diversity of

Figure 6: Average Weighted Diversity of Fathers vs. Turning Angle for Various Plant Densities

fathers as the maximum turning angle increases, see Figure 6. With higher maximum turning angles the search patterns tend to be more circular lowering the overall diversity that a plant will see. On the other hand, by increasing the density, plants will see an increase in diversity due to the larger amount of plants near by. This increase lessens at higher densities due to the limited foraging time of the pollinators.

4 Discussion

There are many factors that affect the dispersal of gene within a species across a landscape. Each factor may have a large effect on particular statistics such as the average or the maximum pollination distance. Each of these statistics as well as the actual factors are difficult if not impossible to accurately measure in the field. The simulations studied here provide insight to the effects of plant density as well as a reasonable model for pollinator movement across the landscape.

The majority of models studying pollination have assumed a purely random diffusion process. There is clear evidence that there are differences in statistics seen between plants pollinated through wind dispersal from those pollinated through animal dispersal, see ***. It is demonstrated here through an agent based correlated random walk that if an animal is not moving in a purely random fashion, then important pollination statistics can be dramatically affected.

As can be seen in the results section the magnitude of turning angle had varying degrees of effects over different plant densities and therefore pollination patterns predicted by a model assuming a purely random walk could be vastly different from a model assuming a correlated random walk. For high plant densities, the effects of correlated random walk was less pronounced than that of low plant densities, except for the *average weighted diversity of fathers*. In the case of *average weighted diversity of fathers* the affect of turning angle magnitudes were more pronounced for high densities. Therefore, although dif-

fusion models for densely populated plant species may not vary greatly from models that assume a correlated random walk for *average pollination distance* or *average maximum pollination distance* they will vary significantly for *average weighted diversity of fathers*. This has the affect of under estimating the diversity of pollination for high plant densities and animal dispersal as compared to similar plant densities and wind dispersal.

The variation between correlated random walk and that of a purely random walk is significant at low plant densities for the statistics such as *average maximum distance*, *average pollination distance*, and *average maximum pollination distance* and so for the case of low plant densities the assumption of a purely random walk may lend to bias in the analysis of pollination. Most studies to date have been conducted on small herbaceous plant species whose densities tend to be high. Even though most of the animals statistics presented were not greatly affected by turning angle for high plant densities the average weighted diversity of fathers had was still greatly affected by the turning angle at these densities, and therefore an assumption of a purely random walk would be an inappropriate assumption and at any of the densities examined in this study. Therefore a correlated random walk may be a better approximation to animal movement.
